Keywords: Hydrothermal Convection, Reservoir Engineering, Pattern Formation

ABSTRACT

Hydrothermal convection in porous media is an essential piece of physics in geothermal reservoirs, and understanding them leads to better development of geothermal energy. We analyze the validity of simulating hydrothermal convection using different formulations of partial differential equations. Using the Elder problem as a benchmark, we found out that the stream function formulation and the velocity formulation are a valid and efficient model of hydrothermal convection. The Nusselt number is a measurement of the quality of convective heat transfer. The Rayleigh number describes the physical properties of porous media. We use simulations to investigate further the discrepancy in the Nusselt-Rayleigh relationship found in previous experiments. The conclusion is that the multiple steady-states of convection patterns in a 3D box are the main reason for the discrepancy found in the Nusselt-Rayleigh relationship.

1. INTRODUCTION

Consider a geothermal reservoir as a box full of porous media heated from below. Natural convection is the dominant driving force of fluids in such a system. For instance, the up-flow of hot fluids can cause shallow-high temperature anomalies. Due to this effect, the high-temperature region is closer to the surface. Therefore, the upflow region of natural convection is preferential for drilling and geothermal exploitation. At present, most conventional geothermal systems operate on such hydrothermal convective systems. A better understanding of natural convection in porous media can lead us to better decisions concerning designing injection and reinjection strategies of a geothermal power plant.

Therefore, we investigate the validity of different partial differential equations that model the natural convection problem. Can the modified equation solve the same physical problem? Can we use different formulations of the same equation to achieve more efficient simulations? We answer these questions using various benchmarks. Our goal is to build an efficient simulation tool that deals with large or maybe previously unsolvable problems.

Modeling natural convection in geothermal systems has become more prevalent. Lipsey et al. (2016) performed numerical simulations of thermal convection in the Lutetgeest carbonate platform and calibrated different models that match the observed temperature data. Niederau et al. (2017) compared simulations of thermal convection in the Perth Basin using homogeneous and heterogeneous permeability scenarios. Straus and Schubert (1979) found out multiple steady-states of convection patterns exist in a 3D box and suggested further research in the indeterminacy of steady-states using a probabilistic manner. The results of the above-mentioned research all showed the unpredictability of natural convection, that the convection pattern can change greatly by perturbing the state of the system (permeability, heterogeneity, the height of the reservoir, boundary conditions, etc.).

Compared to a conductive system, a convective system has a higher capability of heat transfer. A qualitative measure of the quality of convective heat transfer is the Nusselt number (\textit{Nu}), which is the ratio of convective heat transfer to conductive heat transfer. The straightforward question would be: “Given a geothermal reservoir, how well can it transfer heat to the surface?” We use the Rayleigh number to quantify the combined characteristics of any given reservoir, under physical assumptions mentioned in Horne (1979):

- The Boussinesq assumption.
- Inertial effects are small, low Reynolds number.
- Viscosity is constant.
- Thermal dispersion is negligible.
- Saturating fluid and porous solid are in thermal equilibrium.

Experiments that investigate the relationship between the Nusselt number and the Rayleigh number (abbreviated as \textit{Nu-Ra} relation) are performed using the Hele-Shaw cell analogy [Elder (1967a)] or a box full of porous media heated from below [Schneider (1963)] [Yen (1974)] [Kaneko et al. (1974)] [Combarnous and Bories (1975)] [Buretta and Berman (1976)]. Numerical experiments are performed to investigate the upper bound of the \textit{Nu-Ra} relation [Combarnous and Bia (1971)] [Gupta and Joseph (1973)] [Straus (1974)] [Otero et al. (2004)]. Cheng (1979) compiled the \textit{Nu-Ra} relation from some of the previously mentioned research papers, and the results are scattering even in the region of low Rayleigh number (\textit{Ra}<200).

In a 3D box filled with saturated porous media, convection can happen in a two or three-dimensional setting. Straus and Schubert (1979) found out that two-dimensional flows have larger Nusselt numbers than three-dimensional flows when \textit{Ra}<97 using numerical simulations, and vice versa for \textit{Ra}>97. The numerical simulations of Holst and Aziz (1972) and Horne (1979) also produced this effect. If both two and three-dimensional convection can exist in a box filled with porous media, then the system can at least have two Nusselt numbers. The result of Straus and Schubert (1979) indicates that it is always possible to force either steady two-
dimensional or steady three-dimensional convection by proper choice of initial conditions and that random initial conditions lead to either steady two-dimensional or steady three-dimensional convection. Beck (1972) showed that different box sizes favor 2D or 3D convection patterns using analytical methods.

Lister (1990) performed experiments using a large porous slab with two different porous media (a matrix of rubberized curled coconut fiber and clear polymethylmethacrylate beads) and concluded that the discrepancy of the Nu-Ra relation is caused by lateral thermal dispersion. Vadasz (2010) uses an analytical technique to explain the discrepancy of the Nu-Ra relation and concluded that weak boundary and domain imperfections are the reasons for the widespread relation. Lister (1990) and Vadasz (2010) explain this discrepancy from an experimental point of view, that we cannot perform perfect experiments. Therefore, we use simulations to overcome these experimental imperfections. We would like to propose a new explanation for the Nu-Ra relation using simulations.

We hypothesize that the discrepancy of the Nu-Ra relation is not only caused by lateral thermal dispersion and boundary imperfections but also caused by the multiple steady-states of convection patterns. Börsing et al. (2017) observed multiple possible convection modes in 2D boxes at the Rayleigh number regime above the critical Rayleigh number. Kimura et al. (2016) performed simulations in a 2D box and plotted the Nu-Ra relation with different convection modes when 100 ≤ Ra ≤ 400. We investigate the Nu-Ra relation in a 3D box using the proposed finite element solver.

Different convection patterns give us a different quality of heat transfer. In a geothermal production setting, it is beneficial to enhance the Nusselt number. Using a injection-production doublet problem, we briefly investigate the possibility of changing convection patterns by velocity field perturbations. In the following sections, we discuss the detailed setup of the simulations and various benchmarks in section 2. The Nusselt-Rayleigh relationship and the results of the doublet problem are presented in section 3. Section 4 and 5 are dedicated to the discussion of the results and the conclusion of this work, respectively.

2. MATERIALS AND METHOD

2.1 Governing Equations

In this section, we introduce mass, momentum and energy conservation laws that describe natural convection in porous media.

2.1.1 Mass Conservation

We assume the fluid in the reservoir is single phase and incompressible. This incompressibility of fluid is also the result of the Boussinesq approximation. We introduce this divergence-free condition of the Darcy velocity $q$

$$\nabla \cdot q = 0,$$

$$q = \phi \nu,$$

$$q = (u, v, w).$$

where $\phi$ is the porosity, $\nu$ is the seepage velocity. The Darcy velocity composes of three components $u$, $v$ and $w$, which are the Darcy velocity in $x$, $y$ and $z$ directions, respectively.

2.1.2 Momentum Conservation

Darcy’s law is suitable for modeling fluid flow in porous media, such as groundwater or geothermal reservoirs. It defines a relation between the pressure $p$ and the Darcy velocity $q$. Geothermal reservoirs, particularly those found in volcanic rocks, are frequently highly fractured, and for many purposes, the fracturing is sufficiently dense and pervasive on a field scale such that the medium is considered homogeneous [Grant and Bixley (2011)]. Therefore, we introduce the generalization of Darcy’s law in an isotropic and homogeneous medium [Bear (1972)]

$$q = -\frac{K}{\mu} (\nabla p - \rho_f g),$$

where $K$ is the permeability of the reservoir, $\mu$ is the dynamic viscosity of the fluid and $g$ is the gravity.

2.1.3 Energy Conservation

An advection-diffusion equation is used to model the transport of temperature $T$. We assume a simple situation in which the medium is isotropic and where radiative effects, viscous dissipation, the work done by pressure changes are negligible, and there is a local thermal equilibrium of solid and fluid phases [Nield and Bejan (2017)].

$$\frac{\partial}{\partial t} ((\rho c)_m T) + \nabla \cdot (\rho_f c_f T) - \nabla \cdot (k_m \nabla T) = 0,$$

$$(\rho c)_m = (1 - \phi) \rho_s c_s + \phi \rho_f c_f,$$

$$k_m = (1 - \phi) k_s + \phi k_f,$$

where $(\rho c)_m$ is the overall heat capacity per unit volume, and $k_m$ is the overall thermal conductivity. The subscript $s$ and $f$ refers to solid and fluid, respectively.

2.1.4 Equation of State

We introduce an equation of state that couples fluid density and temperature
where $\rho_0$ is the fluid density at some reference temperature $T_0$, and $\alpha$ is the coefficient of thermal expansion. We assume the dynamic viscosity of fluid $\mu$ is constant.

2.2 Nondimensionalized Equations

There are many good analytical and numerical reasons for using nondimensionalized equations with proper scaling. The idea on which dimensional analysis is based is very simple, and can be understood by everybody: physical laws do not depend on arbitrarily chosen basic units of measurement [Barenblatt (1996)]. Nowadays, the greatest practical benefit of scaling is related to running numerical simulations, since scaling greatly simplifies the choice of values for the input data and makes the simulation result more widely applicable [Langtangen and Pedersen (2016)]. Due to the finite representation and nonuniform distribution of floating-point values [Goldberg (1991)], it is, in general, better to scale the problem such that the quantities entering the computations are of unit size (or at least moderate) instead of being very large or very small [Langtangen and Pedersen (2016)].

We follow the derivation by Fowler (1997) closely, with changes in the scaling of pressure $p$, and the Darcy velocity $q$. The scaling factors are chosen such that the momentum equation and the energy equation both share some part of the dimensionless number

\[ Ra = \left( \frac{\rho_0 C_v}{\mu} \right) g \alpha K_d \frac{c_f}{d} \Delta T \]

where $\Delta T$ is the temperature difference between the top and bottom boundaries of the reservoir and $d$ is the depth of the reservoir. The nondimensionalized equations are

\[ \nabla \cdot q = 0, \]
\[ q = -\nabla p + \sqrt{Ra} T_j, \]
\[ T_t + \sqrt{Ra} q \cdot \nabla T - \nabla^2 T = 0, \]
\[ Ra = \left( \frac{\rho_0 C_v}{\mu} \right) g \alpha K_d \frac{c_f}{d} \Delta T, \]

where $Ra$ is the Rayleigh number. We abbreviated the partial derivatives w.r.t time by a subscript of $t$. In the following subsubsections, we review various formulations that solve the natural convection problem.

2.2.1 The Pressure Formulation

A direct way to solve the system of equations is to plug Darcy’s law Eq. (2) into the divergence-free condition Eq. (1)

\[ \nabla \cdot (-\nabla p + \sqrt{Ra} T_j) = 0. \]

Exchange the Darcy velocity term in Eq. (3) by Darcy’s law Eq. (2), and we have the system of equations that couples pressure and temperature

\[ T_t - \sqrt{Ra} \nabla p \cdot \nabla T + Ra T \frac{\partial T}{\partial y} - \nabla^2 T = 0. \]

Even though we try to separate the Rayleigh number into two equations by choosing appropriate scalings, it remains in the convection term in the $y$-direction. In a finite element solver, the mesh should be refined enough such that numerical oscillations of temperature do not appear. Furthermore, in the variational form of the pressure diffusion equation, the no-flux boundary condition is only weakly imposed. Horne (1979) compared finite difference implementations between the pressure formulation and the velocity potential formulation (which we refer to as the stream function formulation) and found out that the latter can be solved much faster and more accurate. Therefore, the pressure formulation is presented here only for completeness. It will not appear in further discussions.

2.2.2 The Stream Function Formulation

The derivation of the stream function formulation closely follows the Ph.D. thesis of Horne (1975). In natural convection problems, pressure boundary conditions are hard to define. Thus we define a stream function $\psi$ that automatically satisfies the divergence-free condition of the Darcy flux

\[ u = \frac{\partial \psi}{\partial y}, \quad v = -\frac{\partial \psi}{\partial x}. \]

Curl Eq. (2)
\( V \times q = V \times (-\nu p + \sqrt{Ra} T) \). \hspace{1cm} (4)

Expand and multiply Eq. (4) by \(-1\)
\[
\frac{\partial u}{\partial y} - \frac{\partial v}{\partial x} + \sqrt{Ra} \frac{\partial T}{\partial x} = 0.
\] \hspace{1cm} (5)

Replace the Darcy fluxes in Eq. (5) and Eq. (3) by the stream function \( \psi \)
\[
\frac{\partial^2 \psi}{\partial x^2} + \frac{\partial^2 \psi}{\partial y^2} + \sqrt{Ra} \frac{\partial T}{\partial x} = 0,
\]
\[
T_t + \sqrt{Ra} \left( \frac{\partial \psi}{\partial y} \frac{\partial T}{\partial x} - \frac{\partial \psi}{\partial x} \frac{\partial T}{\partial y} \right) - \nu^2 T = 0.
\]

This is the stream function formulation in 2D. The boundary conditions for a confined box are simple, \( \psi = 0 \) on the top, bottom, left and right boundaries. We derive the stream function formulation in 3D, followed by Horne (1979) and Hewitt et. al. (2014). Expand Eq. (4) in 3D with three Darcy velocity components \( (u, v, w) \)
\[
\frac{\partial w}{\partial y} - \frac{\partial v}{\partial z} = -\sqrt{Ra} \frac{\partial T}{\partial z},
\]
\[
\frac{\partial u}{\partial z} - \frac{\partial w}{\partial x} = 0,
\]
\[
\frac{\partial v}{\partial x} - \frac{\partial u}{\partial y} = \sqrt{Ra} \frac{\partial T}{\partial x}.
\] \hspace{1cm} (6)

Define a stream function \( \psi = (\psi_1, 0, \psi_2) \) which is divergence-free
\[
q = V \times \psi,
\]
\[
V \cdot \psi = 0.
\] \hspace{1cm} (7)

Exchange the Darcy velocity by stream functions in Eq. (6), and invoke the divergence-free condition of the stream functions Eq. (7)
\[
-\nabla^2 \psi_1 = -\sqrt{Ra} \frac{\partial T}{\partial z},
\]
\[
-\nabla^2 \psi_2 = \sqrt{Ra} \frac{\partial T}{\partial x}.
\]

Substitute the Darcy velocities in Eq. (3) with the stream functions
\[
T_t + \sqrt{Ra} \left( \frac{\partial \psi_1}{\partial y} \frac{\partial T}{\partial x} + \left( \frac{\partial \psi_1}{\partial z} - \frac{\partial \psi_1}{\partial x} \right) \frac{\partial T}{\partial y} - \frac{\partial \psi_1}{\partial y} \frac{\partial T}{\partial z} \right) - \nu^2 T = 0.
\]

For a confined box, the boundary conditions of the stream functions are straightforward
\[
\psi_1 = 0, \text{ on } z = 0.1 \text{ and } y = 0.1,
\]
\[
\psi_2 = 0, \text{ on } x = 0.1 \text{ and } y = 0.1.
\]

However, when there is production or injection of fluids into the box, the boundary conditions of stream functions are not that easy to define. Therefore, we introduce the velocity formulation, which solves the Darcy velocities directly.

### 2.2.3 The Velocity Formulation

This derivation is followed by Beck (1972), Florio (2014), Grodzka-Lukaszewska et. al. (2017). Instead of defining a stream function, we directly combine the divergence-free condition Eq. (1) and the vorticity equation Eq. (4) to form a velocity based formulation. Partially differentiate the vorticity equation Eq. (5) with respect to \( x \) and \( y \)
\[
\frac{\partial^2 \psi}{\partial x \partial y} - \frac{\partial^2 \psi}{\partial y^2} + \sqrt{Ra} \frac{\partial^2 T}{\partial y^2} = 0,
\]
\[
\frac{\partial^2 \psi}{\partial y \partial x} + \sqrt{Ra} \frac{\partial^2 T}{\partial x \partial y} = 0.
\]

Partially differentiate the divergence-free condition Eq. (1) with respect to \( x \) and \( y \), and rearrange
\[
\frac{\partial^2 \psi}{\partial x \partial y} = -\frac{\partial^2 u}{\partial x^2}.
\]
\[
\frac{\partial^2 u}{\partial x \partial y} = -\frac{\partial^2 v}{\partial y^2}.
\]

Exchange the cross differentiation terms
\[
\nabla^2 u + \sqrt{Ra} \frac{\partial^2 T}{\partial x \partial y} = 0,
\]
\[
\nabla^2 v - \sqrt{Ra} \frac{\partial^2 T}{\partial x \partial z} = 0.
\]

Combined with Eq. (3), we have the 2D velocity formulation. The 3D velocity formulation can be obtained using the same technique. They are
\[
\nabla^2 u + \sqrt{Ra} \frac{\partial^2 T}{\partial x \partial y} = 0,
\]
\[
\nabla^2 v - \sqrt{Ra} \left( \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial z^2} \right) = 0,
\]
\[
\nabla^2 w + \sqrt{Ra} \frac{\partial^2 T}{\partial y \partial z} = 0.
\]

The boundary conditions of a confined box are straightforward. The velocity formulation allows us to set inflow and outflow boundary conditions easily.

2.3 Finite Element Methods and Variational Formulations

We solve the stream function formulation and the velocity formulation using MOOSE Framework [Gaston et al. (2009)], a finite element solver. The weak form is formulated by multiplying the partial differential equations by a test function \( \omega \) and integrating over the computational domain \( \Omega \).

The weak form of the stream function formulation in 2D is
\[
\int_{\Omega} \left( \nabla \omega \cdot \nabla \psi + \sqrt{Ra} \frac{\partial \omega}{\partial x} T \right) d\Omega = 0,
\]
\[
\int_{\Omega} \omega T d\Omega + \sqrt{Ra} \int_{\Omega} \omega \left( \frac{\partial \psi}{\partial y} \frac{\partial T}{\partial x} - \frac{\partial \psi}{\partial x} \frac{\partial T}{\partial y} \right) d\Omega + \int_{\Omega} \nabla \omega \cdot \nabla T d\Omega = 0.
\]

We have to add a divergence-free condition of the stream functions \( \psi_1 \) and \( \psi_2 \) for the stream function formulation in 3D. Therefore, the weak form of the stream function formulation in 3D is
\[
\int_{\Omega} \omega \left( \frac{\partial \psi_1}{\partial x} + \frac{\partial \psi_2}{\partial z} \right) d\Omega = 0,
\]
\[
\int_{\Omega} \left( \nabla \omega \cdot \nabla \psi_1 - \sqrt{Ra} \frac{\partial \omega}{\partial x} T \right) d\Omega = 0,
\]
\[
\int_{\Omega} \left( \nabla \omega \cdot \nabla \psi_2 + \sqrt{Ra} \frac{\partial \omega}{\partial x} T \right) d\Omega = 0,
\]
\[
\int_{\Omega} \omega T d\Omega + \sqrt{Ra} \int_{\Omega} \omega \left( \frac{\partial \psi_1}{\partial y} \frac{\partial T}{\partial x} + \left( \frac{\partial \psi_1}{\partial x} - \frac{\partial \psi_2}{\partial y} \right) \frac{\partial T}{\partial y} - \frac{\partial \psi_2}{\partial z} \frac{\partial T}{\partial z} \right) d\Omega + \int_{\Omega} \nabla \omega \cdot \nabla T d\Omega = 0.
\]

The weak form of the velocity formulation in 2D is
\[
\int_{\Omega} \left( \nabla \omega \cdot \nabla u + \sqrt{Ra} \frac{\partial \omega}{\partial x} \frac{\partial u}{\partial x} \right) d\Omega = 0,
\]
\[
\int_{\Omega} \left( \nabla \omega \cdot \nabla v - \sqrt{Ra} \frac{\partial \omega}{\partial x} \frac{\partial v}{\partial x} \right) d\Omega = 0.
\]

The weak form of the velocity formulation in 3D is
The weak form of the energy conservation equation is

\[
\int_{\Omega} \left( \nabla \cdot \nabla \omega \cdot u + \sqrt{R} \left( \frac{\partial \omega}{\partial x} \frac{\partial T}{\partial x} + \frac{\partial \omega}{\partial y} \frac{\partial T}{\partial y} \right) \right) d\Omega = 0,
\]

\[
\int_{\Omega} \left( \nabla \cdot \nabla \omega \cdot v - \sqrt{R} \left( \frac{\partial \omega}{\partial x} \frac{\partial T}{\partial x} + \frac{\partial \omega}{\partial z} \frac{\partial T}{\partial z} \right) \right) d\Omega = 0,
\]

\[
\int_{\Omega} \left( \nabla \cdot \nabla \omega \cdot w + \sqrt{R} \left( \frac{\partial \omega}{\partial y} \frac{\partial T}{\partial y} \right) \right) d\Omega = 0.
\]

The weak form of the energy conservation equation is

\[
\int_{\Omega} \omega T d\Omega + \sqrt{R} \int_{\Omega} \omega q \cdot \nabla T d\Omega + \int_{\Omega} \nabla \omega \cdot \nabla T d\Omega = 0.
\]

We use the Crank-Nicolson time integration scheme and the time step \(\Delta t\) is defined such that the CFL number [Courant et al. (1967)] is less than one. The code is provided in https://github.com/pwhuang/beagle.

### 2.4 Quality Measures of Convective Heat Transfer

The Nusselt number is used to measure the quality of convective heat transfer in our simulations, and it is defined as the ratio of convective heat transfer and conductive heat transfer. Due to its simplicity and practical reasons, the Nusselt number is widely used in experiments as a quality measure of convection. The Nusselt number is

\[
Nu = \frac{h_1}{h_2} \int_0^{h_2} \int_0^{h_1} \left. \frac{\partial T}{\partial y} \right|_{y=1} \ dx \ dz,
\]

where \(h_1\) and \(h_2\) are the length (x-direction) and the depth (z-direction) of the box. This definition is analogous to Hewitt et al. (2014), except that they defined the Nusselt number using the heat flux on the bottom boundary.

### 2.5 Benchmark Problems

We present the following benchmark problem to validate our finite element implementation of the stream function formulation and the velocity formulation.

#### 2.5.1 The Elder Problem

Elder studied convection caused by localized heating using the Hele-Shaw cell experiment and numerical methods [Elder, 1967b]. It is one of the benchmark problems in software such as FEFLOW [Trefry and Muffels (2007)], SUTRA [Voss (1984)] and HydroGeoSphere [Brunner and Simmons (2012)] [Simmons and Elder (2017)]. The boundary conditions of the Elder problem are defined in Figure 1.

![Figure 1: The boundary conditions of nondimensionalized temperature for the Elder problem.](image)

We use the physical parameters of the Elder problem defined by Graf and Boufadel (2011), listed in Table 1.

**Table 1: Physical parameters used for the Elder problem. Modified from [Graf and Boufadel (2011)].**

Combining the physical parameters, we have the Rayleigh number of 521.3. The time scale is roughly 200 years for one nondimensionalized time. We compare our simulations using the stream function formulation and the velocity formulation with the simulation results of HydroGeoSphere at 2, 5 and 10 years [Graf and Boufadel (2011)]. Since the velocity formulation sets up the other problems with injection and production wells easier, we only focus on benchmarking with the velocity formulation in the later sections.

---

**2.5.2 Horne's Experiment**

Horne (1975) performed experiments using a Hele-Shaw cell analogy with Rayleigh number equals to 1000 and 1600. One of the experiments is half heated from the bottom, like the Elder problem cut in half from the middle. Although this experiment is not a standard benchmark of the thermal-hydraulic problems, it is still worth testing to see if our code implementation can realize its unsteady oscillatory behavior. A direct quote from Horne (1975): “The pattern soon becomes largely unicellular and instead of irregular fluctuations the behavior is oscillatory, periodically generating ‘tongues’ of fluid in the ascending and descending regions of the flow.” The results in Figure 3 also produced this oscillatory behavior and the 'tongues' are there.
2.5.3 Beck’s Box

Beck (1972) derived the preferred cellular mode during the onset of convection of a 3D box full of saturated porous media. We benchmark our code implementations using different boxes with lengths $h_1$ and depths $h_2$. We use the notation of $[h_1, h_2]$ to represent the box dimensions. The boxes we chose are $[1.2, 1.2]$, $[2.0, 0.5]$, $[3.0, 1.0]$. The Rayleigh number is set as 42.25, above the critical Rayleigh number, such that the system starts convecting. The initial condition of temperature is the conductive solution with a ±1% perturbation. The results are in Table 2, and they agree with Beck’s analytical cellular modes.

<table>

Table 2: Comparison of Beck’s cellular mode and the simulated cellular mode.

2.6 The Nusselt-Rayleigh Relation

We test the hypothesis by simulating three boxes of different sizes that have two or three-dimensional preferred convection patterns during the onset of convection. The long boxes with sizes of $[1.5, 1.0]$ and $[2.3, 0.9]$ convect with a 2D convection pattern during the onset of convection, and the wide box $[2.5, 1.5]$ convects with a 3D one. The three boxes are tested in the regions of $4\pi^2 \leq Ra \leq 196$ with random initial conditions. The type of convection patterns and the Nusselt number are reported.

2.7 The Injection-Production Doublet Problem

We investigate the possibilities of perturbing the convection states by a typical strategy for geothermal energy production. Consider a doublet system that influences the velocity field of the reservoir. We claim that the pressure flux induced by the well can be defined as a point source of pressure flux on the top boundary. We approximate this point source of pressure flux by a Gaussian function, since
\[ \delta(x - x_i) = \lim_{\sigma \to 0} \exp\left(-\frac{(x-x_i)^2}{2\sigma^2}\right). \]

The effect of wells is, therefore, the sum of the Gaussian functions

\[ v(x, z) = [q] \sum_{i=1}^{N} A_i \exp\left(-\frac{(x-x_i)^2}{2\sigma_{xi}^2} - \frac{(z-z_i)^2}{2\sigma_{zi}^2}\right), \]

where \( A \) is the amplitude of the Gaussian function, \( x_i \) and \( z_i \) are the coordinates of the center of the Gaussian hill, \( \sigma_{xi} \) and \( \sigma_{zi} \) defines how far the well influences the reservoir, and \( N \) is how many wells you have. The flow rate of the Gaussian functions is

\[ Q_i = 2\pi[q]d^2A_i\sigma_{xi}\sigma_{zi}. \]

Say we can introduce a flow rate of \( 10^{-3} \text{ m}^3/\text{sec} \) for both the production and the injection wells to the reservoir. Using the material properties in Table 1, we have

\[ A_i\sigma_{xi}\sigma_{zi} \approx 0.13. \]

We arbitrarily set \( A_i = 13, \sigma_{xi} = \sigma_{zi} = 0.1 \). We use the [1.5, 1.0] box with a Rayleigh number of 43.56, slightly above the critical Rayleigh number as an example, and set the initial condition to the (1, 1) convection pattern. We design two scenarios of the well placement. For scenario 1, we test if we can perturb the convection pattern to another state. We set the center of the effective injection at the coordinate \((x=0.3, y=1.0, z=0.5)\), the center of effective production at \((x=0.7, y=1.0, z=0.5)\), which will lead to a (1, 0) mode.

For scenario 2, both wells are drilled into the downwelling zone of the convection pattern, where a lower temperature fluid is observed. We want to see whether the convection pattern changes, and hotter fluid can be pumped out. We visualize the boundary condition of the Darcy velocity \( v \) at the top boundary in Figure 3.

### 3. RESULTS

#### 3.1 The Nusselt-Rayleigh Relation

We perform simulations of the boxes [1.5, 1.0], [2.3, 0.9] and [2.5, 1.5] while \( 42.25 < Ra < 196 \). See figure 6 for the results.

![Figure 6: Compilation of the Nusselt-Rayleigh relation of the boxes [1.5, 1.0], [2.5, 1.5] and [2.3,0.9].](image)

#### 3.2 The Injection-Production Doublet Problem

To better understand the convection patterns, we perform a Fourier analysis to the convection temperature. The convection temperature is defined as

\[ T_{\text{convect}} = T(x,y,z) - (1 - y). \]
We define \( A_{mn} \) as the amplitude of \( \sin(\pi y) \cos(m\pi x/h_1) \cos(n\pi z/h_2) \). The solution can be approximated by the sum of these functions. We visualize the convection patterns in Figure 7 and 8. Figure 9 shows how the convection patterns change through time.

**Figure 7:** Scenario 1: The change of the convection pattern with respect to time. Left: The \((1, 1)\) initial condition. Middle: The production state at time 0.2 (\( t_2 \)). Right: The perturbed state of \((0, 1)\).

**Figure 8:** Scenario 2: The change of the convection pattern with respect to time. Left: The \((1, 1)\) initial condition. Right: The perturbed state that consists of both \((0, 1)\) and \((1, 0)\) mode.

4. DISCUSSION

4.1 The Nusselt-Rayleigh Relation

We showed that the state of the convection patterns does have an effect on the Nusselt number. When the boxes \([1.5, 1.0]\) and \([2.3, 0.9]\) are in the state of three-dimensional convection \((1, 1)\), they have larger Nusselt numbers compared to the two-dimensional states. This observation agrees with Straus and Schubert (1979), that three-dimensional convection patterns have higher Nusselt number at \( Ra > 97 \). In any of the boxes, we observe jumps of Nusselt number between the different states of convection. To see how multiple steady-state solutions affect the Nusselt-Rayleigh relation, we plot the results of the three boxes over the compilation of Cheng (1979). The Nusselt number in the region of \( Ra < 100 \) shows some discrepancy, but it does not explain the scattering effect well. It can be
possible that some experimental settings of the porous boxes increase the critical Rayleigh number, therefore the onset of convection occurs at a higher Rayleigh number.

The result of $140 < Ra < 196$ shows a wide scattering range of the Nusselt number from 3.212 to 4.145. The first observation is that box sizes do have an effect on the Nusselt number. If we look closer, the boxes are in various convection states in the aforementioned region of Rayleigh number. Given the initial condition of random perturbation of temperature, the solution of our box system does not necessarily converge at the state of maximum heat transfer. Our results agree with the numerical simulations of Straus and Schubert (1979), that both two and three-dimensional convection cells could be obtained at $60 \leq Ra \leq 150$. Therefore, we conclude that multiple steady-states of convection patterns are a reason for the discrepancy of the Nusselt-Rayleigh relation.

4.2 The Injection-Production Doublet Problem

4.2.1 Scenario 1

Scenario 1 investigates how perturbing the velocity field for a relatively short time effect the convection state. When the doublet starts circulating, the amplitude of (1, 0) mode increases and the initial (1, 1) mode fades away. After the circulation stops, the amplitude of (1, 0) mode decreases exponentially. We observed that the amplitudes of both (1, 1) and (0, 1) mode start to increase, and eventually reservoir reaches a steady state of (0, 1) mode. Therefore, we claim that it is possible to change the convection pattern of a geothermal reservoir by the perturbation of the Darcy velocity.

4.2.2 Scenario 2

This scenario investigates whether we can reach a much favorable convective state if the wells are drilled into the downwelling region of the geothermal reservoir. The answer is simply yes. Applying constant circulation for 0.3 nondimensional time, the amplitude of the unfavorable state (1, 1) almost vanished. The convective state reached a combination of two states (1, 0) and (0, 1). This is a favorable state where the upwelling zone reaches the production well, and the downwelling zone reaches the injection well.

Recall that using the physical parameters in Table 1, one nondimensional time represents roughly 200 years. The time scale is proportional to reservoir depth squared. Therefore, if the reservoir depth is halved, we have one nondimensional time equals to 50 years, which is more manageable.

5. CONCLUSION

We use the Elder problem as a benchmark and show that the stream function and the velocity formulations are valid for solving problems of hydrothermal convection in porous media. Using the velocity formulation, we performed the three-box test. It allows us to explain how box sizes and multiple steady-states of convection patterns leads to the discrepancy of the Nusselt-Rayleigh relation in the region of $Ra < 196$.

The fact that

- multiple steady-states of convection patterns exist and
- different convection pattern leads to a different value of Nusselt number
Huang and Wellmann.

tells us that a naturally convected geothermal reservoir may not be in its most efficient state of transferring heat to the surface. We used the doublet problem to show that it is possible to change the convection states from one another by perturbing the velocity field.

NOMENCLATURE

- $Ra$: Rayleigh number
- $Ra_c$: Critical Rayleigh number
- $Nu$: Nusselt number
- $\rho_f$: Density of fluid
- $\rho_s$: Density of solid
- $\Phi$: Porosity of the reservoir
- $\psi$: Stream Function
- $T$: Temperature
- $p$: Pressure
- $q$: Darcy velocity, vector
- $u$: The $x$ component of the Darcy velocity
- $v$: The $y$ component of the Darcy velocity
- $w$: The $z$ component of the Darcy velocity
- $K$: Permeability
- $\mu$: Dynamic viscosity of fluid
- $d$: Depth of the reservoir
- $c$: Heat Capacity
- $\alpha$: Thermal expansion coefficient of fluid
- $g$: Gravity
- $[h_1, h_2]$: Box sizes, $h_1$ is the length in the $x$-direction. $h_2$ is the length in the $y$-direction.
- $(m, n)$: Convection pattern or convection modes
- $\omega$: Test function
